Just Accepted

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.
Titanium Carbide MXene Nucleation Layer for Epitaxial Growth of High-Quality GaN Nanowires on Amorphous Substrates

Abstract

Growing III-nitride nanowires on 2D materials is advantageous as it effectively decouples the underlying growth substrate from the properties of the nanowires. As a
relatively new family of 2D materials, MXenes are promising candidates as III-nitride nanowire nucleation layers capable of providing simultaneous transparency and conductivity. In this work, we demonstrate the direct epitaxial growth of GaN nanowires on Ti$_3$C$_2$ MXene films. The MXene films consist of nanoflakes spray coated onto an amorphous silica substrate. We observed an epitaxial relationship between the GaN nanowires and the MXene nanoflakes due to the compatibility between the triangular lattice of Ti$_3$C$_2$ MXene and the hexagonal structure of wurtzite GaN. The GaN nanowires on MXene show good material quality and partial transparency at visible wavelengths. Nanoscale electrical characterization using conductive atomic force microscopy (C-AFM) reveals a Schottky barrier height of $\sim 330$ meV between the GaN nanowire and the Ti$_3$C$_2$ MXene film. Our work highlights the potential of using MXene as a transparent and conductive pre-orienting nucleation layer for high quality GaN growth on amorphous substrates.

**Keywords**

nanowires, MXene, molecular beam epitaxy, GaN, amorphous substrate

III-nitride nanowires have attracted much attention because of their potential as the main component in optoelectronic devices. Threading dislocation-free nanowires can be grown with reduced strain on various substrates without the requirement of a global epitaxial relationship.\(^{12}\) However, the fabrication of nanowire-based optoelectronic devices typically requires an electrically conductive substrate, which limits the substrate selection.

A possible method of circumventing the substrate limitation is using a 2D material as the nanowire nucleation layer. By utilizing a 2D material as a nucleation layer, the growth of the nanowires is effectively decoupled from the properties of the underlying substrate. The concept of growing III-nitride films and nanostructures on 2D materials including hexagonal boron nitride,\(^{6-8}\) graphene,\(^{9-11}\) and transition metal dichalcogenides (TMDs) such as MoS$_2$\(^{10,11}\) has been demonstrated. The epitaxial relationship between III-nitride and the 2D
material nucleation layer is generally assumed to be based on the van der Waals epitaxy mechanism, allowing high-quality material growth despite the lattice mismatch between the 2D material and III-nitride layers. By taking advantage of this growth property, it is possible to reproduce the growth process on any substrate capable of withstanding the growth process temperature.

Currently, graphene is arguably the most widely studied 2D material. However, the production of graphene thin films is restricted by cost and size limitations in the direct chemical vapor deposition (CVD) synthesis process. Although another deposition method using spray-coating, spin-coating, and dip-coating of reduced graphene oxide (GO) has been developed, this method results in high sheet resistance ($1 - 1000 \, \text{k}\Omega \text{sq}^{-1}$) due to the high inter-flake resistance and defects. Thus, the application of graphene for large-scale applications is limited by these factors.

As a new class of 2D materials, MXenes are thought to be viable alternatives for graphene. MXenes have several advantageous properties, such as high metallic conductivity and partial transparency. The potential for large scale transparent and conductive MXene films has been demonstrated through the spray coating of delaminated Ti$_3$C$_2$T$_x$ nanoflakes, where the transparency can be adjusted from 40% to 90%, while the sheet resistance ranges from 0.5 to 8 k\Omega sq$^{-1}$. This makes MXenes attractive as a transparent conductive layer for large scale applications. The triangular geometry of Ti$_3$C$_2$T$_x$ MXene’s basal plane (a=3.071 Å) match well with that of GaN (3.189 Å), which helps promote the growth of high-quality GaN on top of Ti$_3$C$_2$T$_x$ MXene. The van der Waals epitaxial growth mode of materials such as BaTiO$_3$ on top of MXene has also been demonstrated, which may support applications such as the transfer of GaN nanowires on MXene onto foreign substrates. The work function of heat-treated Ti$_3$C$_2$T$_x$ MXene (4.28 eV) is comparable to the work function of Ti (4.33 eV), which is a metal commonly used to form ohmic contact to $n$-GaN. Currently, no III-nitride growth on MXene has been reported. Thus, the study of III-nitride nanowire growth on MXene is an interesting topic, as it will introduce another possible 2D material
family for the growth and fabrication of III-nitride devices.

In this work, we demonstrate the epitaxial growth of III-nitride nanowires directly on Ti$_3$C$_2$ MXene using plasma-assisted molecular beam epitaxy (PA-MBE). We observed an epitaxial relationship between the MXene film and the in-plane orientation of the GaN nanowires, which suggests that the triangular lattice of the Ti$_3$C$_2$ MXene plays a role in adjusting the in-plane orientation of the GaN nanowires. Our analysis shows that MXenes are promising as transparent and conductive nucleation layers for epitaxial growth of GaN nanowires on amorphous substrates.

Results and Discussion

The structure of GaN nanowires grown directly on Ti$_3$C$_2$ MXene nanoflakes is depicted in Figure 1 (a). To evaluate the feasibility of using MXene film for high-temperature growth we loaded a fused silica substrate coated with Ti$_3$C$_2$ MXene film into the MBE buffer chamber and annealed it. The annealing was performed at 750°C under a base pressure of $1 \times 10^{-9}$ Torr, which is a typical growth temperature of GaN by MBE. After the annealing process was complete, we performed a Raman spectroscopy on the MXene film. All Raman measurements were performed under a non-polarized backscattering configuration using a Horiba Aramis system with a 473 nm laser as an excitation source. The effect of annealing is shown in Figure 1 (b). From the Raman spectra, we see that MXene peak softening occurs. This softening might be attributed to the relocation of oxygen surface functional groups into sites that were previously occupied by the fluorine surface groups before ultra-high vacuum annealing. The desorption of fluorine has been observed after annealing at this temperature. These changes in the Ti-O bond configuration can alter the Raman active vibration modes, resulting in peak softening.

We further investigated the effect of Ti$_3$C$_2$ MXene film on the morphology and quality of the GaN nanowires. We grew GaN nanowires directly on top of bare fused silica, on
a partially covered MXene film, and on a fully covered MXene film as the nucleation layer under nominally identical conditions. The root mean square (rms) roughness for the fused silica, partially covered MXene film, and fully covered MXene film are 0.79 nm, 3.5 nm, and 5 nm respectively. By interpolating the transmittance measurement data with known thickness vs transmittance values, we determine the fully covered MXene film to be about 19.2 nm thick. The growth was performed at 800 °C, with a $2.5 \times 10^{-8}$ Torr gallium beam equivalent pressure, and radio frequency (RF) plasma at 350 W power and 1 sccm nitrogen flow rate. The Raman spectra are shown in Figure 1 (c), while the plan view scanning electron microscopy (SEM) images are shown in Figure 1 (d)-(f).

We investigated the $E_{\text{high}}^2$ phonon mode associated with the wurtzite GaN structure by Raman spectroscopy to evaluate the quality of the GaN nanowires. GaN nanowires grown directly on fused silica grow in a highly dense manner with a high degree of coalescence as shown in Figure 1 (d). The nanowires grow with a random in-plane orientation, which is typical for nanowire growth on amorphous silica surface. The relative intensity of the $E_{\text{high}}^2$ phonon is weaker than the signal from the fused silica, due to the poor quality of the GaN material.

Figure 1 (e) shows the plan view of GaN nanowires grown on a partially covered MXene film. In general, the GaN nanowires coalesce into a compact layer, while in some areas, the nanowires grow with a morphology similar to the morphology of nanowires grown directly on fused silica. Atomic force microscopy (AFM) measurements on the surface (see inset) shows that the fused silica is only partially covered with MXene in a nonuniform manner, resulting in nanowires growing directly on the exposed fused silica. On the other hand, the nanowires grow with high density on top of the MXene nanoflakes, eventually coalescing into a compact layer with hexagonal features on the surface. Figure 1 (f) shows the plan view of GaN nanowires grown on a fully covered MXene film. A clear nanowire morphology with hexagonal facets can be seen. The diameter and density of the nanowires grown on MXene are non-uniform across the substrate surface. Our data show a decrease in nanowire
density with an increasing number of MXene flakes (controlled by changing the number of MXene spray coated layers), which is similar that observed for GaN nanowires grown on multilayer graphene.\textsuperscript{33} As the number of MXene flakes is increased, the nucleation probability of nanowires is decreased, which is caused by elasticity and strain partitioning between the GaN nucleus and the underlying layered material. Thus, the thickness of the MXene film can be used to control the morphology of the GaN nanowires grown on top. Although the fully covered MXene film shows some thickness fluctuations, the fluctuations are considered to be too small to create a significant nanowire morphology variation.

Elevated and cross-section view of the GaN nanowires grown on the fully covered MXene film are shown in Figure 2 (a) and (b), respectively. The nanowires grow perpendicular
to the substrate, with some tilting caused by the uneven surface of the MXene film. The alignment of the nanowires and the interplanar spacing between the MXene monolayers were evaluated using polycrystalline X-ray diffraction (XRD) as shown in Figure 2(c). The $\theta/2\theta$ scan of the GaN nanowire sample shows a dominant Ga(0002) peak and additional Ga(0004) peak, which indicates growth in the c-plane direction typical of spontaneously grown GaN nanowires. The inset shows the Ti$_3$C$_2$ (002) peak, which can be ascribed to the interlayer spacing of the MXene nanoflakes. After nanowire growth occurs, the c lattice parameter of the MXene film decreases as shown by the shift in the Ti$_3$C$_2$ (002) peak. This might be caused by the removal of the intercalated water molecules between the MXene layers during high-temperature annealing in the ultra high vacuum environment. The verticality of the GaN nanowire ensemble is evaluated using the XRD rocking curve of the GaN (0002) peak, shown in Figure 2(d). The (0002) peak has full width at half maximum (FWHM) of 5925 arcsec (1.646°), which is comparable to the FWHM value for GaN nanowires grown on multilayer graphene. The broad FWHM value comes from the misorientation of the GaN nanowire’s verticality due to the thickness variation of the MXene film and variations among the nanowire heights.

From the plan view SEM in Figure 3(a), we observe that nanowires grown close together in a small area exhibit similar in-plane orientations. A lower magnification SEM in Figure 3(b) shows multiple in-plane orientations, as indicated by the false-color map on the SEM image. This is caused by the epitaxial relationship between the nanowires and the underlying MXene nanoflakes. GaN nanowires that grow on the same MXene nanoflake show identical in-plane orientation, which indicates an epitaxial relationship between the first atomic plane of the GaN nanowires and the Ti$_3$C$_2$ MXene.

We performed an XRD measurement on a 1 x 1 cm$^2$ sample to obtain the pole figure of the GaN {10-14} reflection. While GaN nanowires grown on Si(111) typically exhibit six-fold symmetry, Figure 3(c) shows that the GaN nanowires grown on MXene nanoflakes do not exhibit this behavior. Instead, an almost random pattern with some preferred in-plane

(d) XRD Rocking curve of the GaN (0002) peak.
orientation can be seen. The lack of symmetry is attributed to the random in-plane orientation distribution of MXene nanoflakes, which were spray coated on top of the amorphous substrate.

Figure 3: Effect of MXene nanoflakes on the in-plane orientation of GaN nanowires. (a) Plan-view of GaN nanowires grown on MXene. (b) Lower magnification plan-view SEM showing distinct in-plane orientations of the nanowires, as indicated by the false color map. (c) XRD pole figure plot taken from the {10-14} reflection of GaN, showing an almost random in-plane orientation distribution.

The structural properties of GaN nanowires and the interface between the GaN and MXene film were studied using transmission electron microscopy (TEM). Figure 4 (a) shows a low-magnification TEM of the GaN nanowires. A selective area diffraction pattern image was taken of the GaN nanowires, showing single crystallinity. A higher-magnification TEM image showing a single GaN nanowire grown directly on top of the MXene film is shown in Figure 4 (b). The MXene film consists of individual MXene nanoflakes layered on top of each other in a random manner, resulting in a non-uniform film thickness across the substrate. This can be seen by the presence of a step at the base of the nanowire.

The horizontal lines indicated in Figure 4 (b) correspond to an area with a high density of Type $I_1$ basal stacking faults (BSFs). This stacking fault is typically modeled as the insertion of a thin zincblende phase within the wurtzite GaN nanowire matrix. BSFs have been observed in MBE-grown III-nitride nanowires grown on Si$^{30,31}$ and Ti foil,$^{32}$ and are believed to be caused by growth condition instability instead of strain.$^{33}$ By optimizing the
growth condition, it is possible to prevent the formation of BSFs.

A high-resolution high-angle annular dark field (HAADF) image of the interface between the nanowires and MXene is shown in Figure 4 (c). The GaN nanowires grow in the $<0001>$ c-plane direction perpendicular to the substrate and MXene film. The GaN nanowire grows directly on the MXene film without the formation of a polycrystalline wetting layer which has been observed for GaN nanowires grown on nitridized silicon substrate and fused silica substrate.\textsuperscript{32,39} Figure 4 (d) shows an HAADF image of the GaN-MXene film-fused silica interface with the energy-dispersive X-ray (EDX) elemental mapping result superimposed. We captured the EDX signal from Ga, Ti, and Si, which corresponds to the GaN nanowires, MXene film, and fused silica layers, respectively. A clear interface can be seen among the Ga, Ti, and Si signals.

Based on the known lattice constant of both wurtzite GaN and Ti$_3$C$_2$ MXene, we simulated the possible heteroepitaxial relationship between the wurtzite GaN nanowires and the underlying MXene film. As shown in Figure 4 (e,f), the distance between the nearest GaN primitive unit cell along the $<11\text{-}20>$ direction is 3.189 Å, while the distance between Ti atoms along the $<11\text{-}20>$ direction is 3.071 Å. This configuration gives a lattice mismatch of $\sim$3.7\%, allowing for coherent strain between the GaN nanowires and the Ti$_3$C$_2$ MXene film.

Based on the structural characterization that we have performed, Ti$_3$C$_2$ MXene is suitable for the growth of GaN nanowires due to the compatibility between the triangular atomic geometry of MXene and the wurtzite structure of GaN. Due to the surface functional group on the surface of the Ti$_3$C$_2$ MXene nanoflakes, the MXene film has a negative polarity. This negative polarity may serve a similar function as the N-polar surface of AlN nucleation layers for promoting the initial nucleation for nanowire growth.\textsuperscript{40} The surface functional groups consist of oxygen, hydroxyl, and halogen groups; the latter subject to desorption during annealing in ultrahigh vacuum environment. The remaining oxygen and hydroxyl groups can rearrange their site, creating local fluctuation of surface chemistry that can act as nucle-

(b) A high-resolution TEM image GaN nanowire, showing the direct growth of the GaN nanowires on top of the MXene film. The presence of BSFs is indicated by the yellow box. (c) High-resolution HAADF image taken at the interface between the MXene film and GaN base, showing GaN growth in the <0001> direction. (d) A composite HAADF and EDX elemental mapping image showing the composition of Ga, Ti, and Si. (e,f) Schematic images of the atomic configuration representing the heteroepitaxial relationship between the first atomic plane of wurtzite GaN and Ti$_3$C$_2$ Mxene.
ation sites. Thus, Ti$_3$C$_2$T$_x$ may be more advantageous than graphene in promoting nanowire nucleation. However, considering how GaN nanowires can be grown on both polar (N-polar AlN) and non-polar (graphene)	extsuperscript{31} nucleation layer using PA-MBE, the surface polarity might not be the major factor in determining the nucleation of GaN nanowires. Nonetheless, the possible effect of the polarity of MXene and surface functional groups on the nucleation and growth kinetics of GaN nanowires cannot be ruled out.

Transparent devices can be beneficial for applications requiring simultaneous transparency and conductivity, such as photovoltaic solar cells and photoelectrochemical water splitting. The transmittance value for the MXene film and GaN nanowires grown on MXene was evaluated using UV-Vis spectrophotometry, as shown in [Figure 5] (a), with corresponding optical photographs of the samples shown in (b) and (c). For the MXene film, the transmittance value is above 40% for the entire visible wavelength region. After the growth of the GaN nanowires occurred, the transmittance value was reduced. One of the possible causes is light scattering from the ensemble nanowire structure.	extsuperscript{11} Hantasarisakul et al. also observed the relationship between light transmittance through the Ti$_3$C$_2$T$_x$ MXene film and the c-lattice spacing between the MXene nanoflakes, where a larger lattice spacing generally leads to a higher transmittance. Therefore, the reduced MXene c-plane spacing after GaN nanowire growth might also contribute to the reduced transmittance value.	extsuperscript{22} This also highlights the possibility of tuning the transmittance value of the device after growth by introducing an intercalant between the MXene nanoflakes.

To evaluate the optical properties along with the material quality of the GaN nanowires grown on MXene, we performed photoluminescence (PL) measurements at room temperature (RT) and low temperature (4 K) and 244 nm laser excitation. The PL results are summarized in [Figure 5] (d) and (e). The RT PL emission peak is broad with an FWHM of ~40 meV, with multiple peaks visible at low temperature (4 K). Peak deconvolution using the Gaussian peak fitting routine reveals 4 major peaks (FWHM) centered at 3.46 eV (7.34 meV), 3.47eV (10.44 meV), 3.49 eV (19.42 meV), and 3.51 (8.11 meV) respectively. Slightly

altered peak positions and FWHM values can be caused by scattered binding energy values of the excitons resulting from the different growth conditions, the crystallinity of the substrates, residual strain in the heteroepitaxial GaN layers, residual unintentional dopants in the growth chambers, and the excitation power density used.\textsuperscript{32,34,43,46} Low-temperature PL is expected to be dominated by neutral donor-bound exciton transitions (D\textsuperscript{0}X), which we observe at 3.47 eV whereas the peak at the lower energy side of D\textsuperscript{0}X centered at 3.46 eV with an FWHM of 7.34 meV is attributed to the acceptor-bound excitons (A\textsuperscript{0}X).\textsuperscript{46} Even though the GaN nanowires are n-doped, the existence of acceptor-bound excitons can be attributed to the residual impurities in the MBE chamber.\textsuperscript{34,45,46} The two peaks on the higher energy side of D\textsuperscript{0}X are recognized as free exciton related emission, namely FX\textsubscript{A} and FX\textsubscript{B}. The FWHM of the dominant PL peak, D\textsuperscript{0}X, in our case is 10.44 meV, which is narrower than that observed for GaN nanowires grown on graphene,\textsuperscript{34} confirming high crystal quality.

Typically, the fabrication of nanowire-based devices on insulating substrates such as silica requires additional processing steps such as the use of flip-chip configuration.\textsuperscript{47} By using MXene as the nucleation layer for the nanowires, lateral conduction across the insulating substrate is supported. For electrical characterization, the nanowires are probed using conductive AFM (C-AFM). The top of the n-doped nanowires is contacted using a PtIr coated conductive AFM tip without prior. Apart from the standard solvent cleaning procedure, no chemical treatments were performed on the GaN nanowires. In this configuration, the C-AFM tip is grounded, while a bias is applied to the MXene film. The MXene film is electrically contacted to the AFM stage by attaching a copper wire to the area where GaN nanowires do not grow. A simplified schematic of the C-AFM setup is shown in Figure 6 (a). In this setup, a negative current value indicates current flowing from the C-AFM tip to the substrate. We performed a voltage sweep from -6 to 6 V, and the tip current was limited from -10 to 10 nA. Therefore, structural damage due to junction heating in the nanowire is unlikely.\textsuperscript{8}

The PtIr C-AFM tip, the n-GaN nanowire, and the MXene film arrangement create a
metal-semiconductor-metal (MSM) configuration. In the case of heavily doped \textit{n}-type GaN nanowires, thermionic field emission is the dominant mechanism for carrier transport through the Schottky barrier.\footnote{18}

Figure 6 (b) shows the I-V curve obtained from random sampling of multiple nanowires. In general, the turn-on voltage under reverse bias (RB) is lower than the turn-on voltage under forward bias (FB). This can be explained by the difference in the Schottky barrier height at each end of the nanowire, as depicted in Figure 6 (c). To extract the Schottky barrier height at both ends of the nanowires, we performed an MSM fitting routine using the PKUMSM MATLAB script. In the model, the C-AFM measurement configuration is considered to be two Schottky barriers connected back to back, with the nanowire as a resistor in series with the Schottky barriers.\footnote{19} To simplify the fitting process, we used an average nanowire diameter of 60 nm and a height of 150 nm. The effect of applied voltage on the Schottky barrier height is taken into account; thus the fitting routine gives an effective Schottky barrier height. The fitting result is shown in Figure 6 (c). From the fitting parameters, the Schottky barrier height between \textit{n}-GaN and MXene is approximately 330 meV, while the barrier height between \textit{n}-GaN and the PtIr tip is approximately 840 meV.

The large Schottky barrier height between the C-AFM tip and \textit{n}-GaN is expected, as the work function of the PtIr C-AFM tip (\(\sim 5.1\) eV) is significantly larger than the electron affinity \(\chi\) of GaN (4.1 eV).\footnote{50,51} However, the observed value of the Schottky barrier is lower than \(\phi_{\text{PtIr}} - \chi_{\text{GaN}}\) (\(\sim 1\) eV). This difference is caused by the effect of the nanometer-sized contact between the GaN nanowire and the PtIr tip. As the tip of the C-AFM probe (25 nm) is smaller than the average diameter of the nanowires (60 nm), the Schottky metal contact can become unstable, depending on the applied tip force. Furthermore, Jamond \textit{et al.} demonstrated that the Schottky contact area formed between the C-AFM tip and the nanowire is approximately a few nanometers in size. As the contact area is much smaller than the depletion width in GaN nanowires, the conventional Schottky diode description cannot be used.\footnote{50} Furthermore, the GaN nanowires did not undergo chemical treatment before the
C-AFM measurement, which may result in a modified surface potential due to the presence of native surface oxide layer.

On the other hand, the interface between the GaN nanowire and Ti$_3$C$_2$ MXene shows a Schottky contact behavior despite Ti$_3$C$_2$ Mxene and Ti having a similar work function. During the nanowire growth process inside the MBE chamber, we cannot rule out the possibility of carbon or titanium interdiffusion into the GaN nanowire, which may form an interfacial layer or result in unintentional doping at the base of the nanowires. This formation of the interfacial layer may explain the Schottky contact at the interface of the GaN nanowires and the MXene. Exposure to nitrogen plasma has also been shown to induce doping effects in MoS$_2$, which may alter the work function of the MXene film. The Schottky barrier behavior may help in fabricating Schottky-based devices such as piezotronic energy harvesting devices. By adjusting the doping concentration of the $n$-GaN nanowire, it is also possible to promote electron tunneling through the Schottky barrier for optoelectronic device applications.

Conclusions

We have shown that Ti$_3$C$_2$ MXene is suitable as a nucleation layer for GaN nanowire growth on amorphous substrates due to the low lattice mismatch between MXene and GaN nanowires (~3.7%). The MXene nanoflakes can be deposited on a large surface area through the spray coating method, making it attractive for large scale applications. By adjusting the thickness of the MXene film and the growth conditions of the GaN nanowires, a high-quality nanowire structure can be grown directly on MXene films without the need for buffer layers. The epitaxial relationship between Ti$_3$C$_2$ MXene and GaN resulted in an ordered in-plane orientation of the GaN nanowires regardless of the orientation of the underlying substrate. Nanoscale electrical measurements using C-AFM show a Schottky barrier of approximately 330 meV between the GaN nanowire and Ti$_3$C$_2$ MXene film. The transparency, electrical conductivity, and scalability of the GaN nanowire/MXene platform make it attractive for applications such as transparent electronics, solar cells, energy harvesting, and photoelectrochemical water splitting.

Methods

Ti$_3$C$_2$ MXene synthesis: Ti$_3$AlC$_2$ (layered ternary carbide MAX phase) powder was purchased from Carbon-Ukraine Ltd. (particle size < 40µm). One gram of Ti$_3$AlC$_2$ MAX phase powder was slowly immersed into a mixture solution of 20 ml 9 M HCl and 1 g of LiF under magnet stirring that was cooled by an ice bath to minimize localized heat from the initial exothermic reaction. The mixture solution was kept at 35°C with magnet stirring in an oil bath for 24 hours. The mixture was transferred to a centrifuge tube and washed several times with additional deionized (DI) water to make a total volume of 50 ml. Each wash was performed by centrifugation at 3000 relative centrifugal force (RCF) for 5 min. The supernatant was decanted, and the sediment was redispersed into DI water by manual shaking. Once the pH of the supernatant reached approximately 6, the final centrifugation
step was performed at 500 RCF for 30 min after redispersing the sediment in DI water. The supernatant solution containing delaminated 2D MXene nanoflakes was collected and was used for spray coating.

Spray coating of MXene: Double side polish 2" fused silica (Semiconductor Wafer, Inc.) was diced into 1×1 cm² size followed by ultrasonic cleaning by acetone, isopropanol, and dried by nitrogen flow. The fused silica substrate is then treated by UV/ozone treatment for 10 minutes to enhance the surface hydrophilicity. Aqueous Ti₃C₂ MXene suspension with their concentration of ∼ 1.0 – 1.5 mg/ml was sprayed by airbrush (HB-B plus, Iwata, Japan) with a fluid nozzle of 0.2 mm, assisted by pressurized nitrogen gas at ∼ 3.5 – 4.0 bar (∼ 50 – 60 psi). The spray gun was positioned at ∼ 15 – 20 cm away from the substrates. The spray coating was performed in a layer-by-layer manner under mild-warm airflow to accelerate drying until the desired thickness is reached.

III-Nitride nanowire growth: MXene-coated fused silica was cleaned using acetone and isopropyl alcohol, followed by blow drying under nitrogen. No water was used during the cleaning procedure to prevent MXene film delamination. A Veeco Gen 930 MBE chamber with thermal effusion cells and RF plasma source was used. Thermal cleaning was performed inside the MBE preparation chamber at 650 °C under a background pressure of 1×10⁻⁹ Torr. GaN nanowire growth is performed inside the MBE growth chamber under nitrogen-rich conditions. The nucleation and growth of n-GaN was performed using a single growth step at 800 °C. Throughout the growth process, the nitrogen plasma condition was maintained at 1 sccm flow rate with 350 watt RF power.

Photoluminescence measurement: PL measurements were carried out using a 244 nm continuous wave laser, and the emission signal was detected by an Andor Shamrock 303i spectrograph attached to an Andor Newton CCD detector assisted with 299 lines/mm grating blazed at 300 nm, where the laser spot size was focused to ∼100µm. The acquisition time used was 1 second for a 10 measurement integration. A closed cycle refrigerator ARS cryostat was employed for cryogenic measurements. PL spectra comparison between RT and 4 K was
performed with a PL excitation power density of 22.29 W cm$^{-2}$, and 4 K spectra acquisition for deconvolution was performed under a PL excitation power density of 3.18 W cm$^{-2}$.

Raman spectroscopy: Raman spectroscopy was performed in an unpolarized backscattering configuration using a Horiba Aramis system with a 473 nm laser excitation.
